We consider electro-weak Higgs plus three jets production at NLO QCD beyond strict VBF acceptance cuts. We investigate, for the first time, how accurate the VBF approximation is in these regions and within perturbative uncertainties, by a detailed comparison of full and approximate calculations. We find that a rapidity gap between the tagging jets guarantees a good approximation, while an invariant mass cut alone is not sufficient, which needs to be confronted with experimental choices. We also find that a significant part of the QCD corrections can be attributed to Higgs-Strahlungs-type topologies.

Introduction – In 2012 both the ATLAS [1] and CMS [2] collaborations announced the discovery of a new boson in the mass range of 125–126 GeV [3, 4]. There were indications that this new particle behaved very similar to the Higgs boson of the Standard Model [5–12] and recently, the ATLAS and CMS collaborations reported the Standard Model hypothesis to be consistent with data in a combined analysis of LHC proton-proton collision data at $\sqrt{s} = 7$ and 8 TeV [13]. The Vector-Boson Fusion (VBF) signature [14–29] is among the most important production channels of the Higgs boson in the ongoing run of the Large Hadron Collider (LHC). For a Higgs boson accompanied by at least two jets in the final state, the underlying production processes allow for both space-like, t -channel, exchange of weak gauge bosons producing a Higgs boson, as well as time-like Higgs-Strahlung type topologies of associated production with a vector boson which decays into a quark–anti-quark pair, cf. Fig 1. All of the contributing diagrams do interfere, and the VBF region is usually referred to as a phase space region in which one expects the t -channel diagrams to dominate, with time-like s -channel and interference effects broadly suppressed. In the VBF region one requires two highly energetic jets, well separated in rapidity and with the Higgs boson decay products located in the central detector region and possibly in between the two jets. Additionally, a veto on central QCD activity is sometimes applied to enrich the contribution of the colour singlet vector boson exchange [30–35].

Theoretical predictions in this region often employ the so-called VBF approximation, where only the t -channel topology is kept and s -channel contributions as well as interference effects between different topologies are neglected. Fig 1 gives an example of some of the contributions which are typically not considered. Formally, this corresponds to the approximation that the constituents of the two incoming protons belong to two dif-

FIG. 1. In the VBF region interferences among certain t -channel topologies (top diagram) as well as t/s -channel (lower diagram, and t/u -channel, not depicted) interferences are neglected. In these diagrams wavy lines represent electroweak bosons, dotted lines the Higgs boson, curly lines are gluons and solid arrowed lines are quarks. The dashed vertical line represents the final state cut.

ferent, but otherwise identical, copies of the colour gauge group $SU(3)$. Recent experimental analyses do not implement selection criteria for the VBF region as tight as originally envisaged [14–20], and rely on a multitude of multi-variate analysis techniques instead [36]. While for the Higgs plus two jet case the validity of the VBF approximation has been confirmed within a tight selection [21, 22], essentially nothing is known quantitatively for additional radiation as relevant to the veto on central jets (CJV), or virtually any observable exploiting properties of the radiation pattern of the underlying electro-weak production process.

Next-to-leading order corrections in Quantum Chromodynamics (QCD) to the three jet process are available without any approximation [37] as a plugin to the Matchbox framework [38] of the Herwig 7 event generator [39–41], and can be compared to calculations based on the VBF approximation [42] as implemented in the VBFNLO program [43–45]. In this letter we quantify the reliability of the VBF approximation, *i.e.* the neglect of the diagrams which are not of the VBF t -channel topology along with interference effects with u -channel topologies.

Outline of the calculation – We use the Herwig 7 event generator in its recent release 7.1.2 [40, 41], together with HJets++ 1.1 [46] to provide the amplitudes for electroweak Higgs boson plus jets production. The colour structure is treated using ColorFull [47] and the loop integrals are computed following Ref. [48]. For the VBF approximation we rely on the approximate calculation provided by VBFNLO version 3.0 beta 5. Both calculations have recently also been interfaced to parton showers using different matching paradigms, for a dedicated comparison see [49, 50]. The one-loop matrix elements of HJets++ and VBFNLO have been cross-checked against those of MadLoop [51], GoSam 2.0 [52], and OpenLoops [53] at the level of phase space points.

We have ensured that both programs run with the same set of electroweak parameters in a G_μ scheme with input parameters $G_F = 1.16637 \times 10^{-5} \text{ GeV}^{-2}$, $M_Z = 91.1876 \text{ GeV}$ and $M_W = 80.403 \text{ GeV}$. The electromagnetic coupling constant and the weak-mixing angle are calculated via tree level relations. We take the Higgs boson as stable, with a mass fixed to $m_H = 125.7 \text{ GeV}$. The widths of the bosons are fixed to $\Gamma_Z = 2.4952 \text{ GeV}$ and $\Gamma_W = 2.141 \text{ GeV}$. We consider proton-proton collisions at 13 TeV center of mass energy and employ a four-flavour scheme with the MMHT 2014 68% C.L. PDF set at NLO [54] with a two-loop running α_s set at $\alpha_s(M_Z) = 0.12$ with $m_c = 1.4 \text{ GeV}$ and $m_b = 4.75 \text{ GeV}$.

We select jets using the anti- k_\perp algorithm as implemented in the fastjet library [55, 56], with a cone radius of $R = 0.4$, and accept jets ordered in transverse momentum, with a transverse momentum $p_{\perp,j} > 30 \text{ GeV}$ inside a rapidity range of $|y_j| < 4.4$. No restrictions are applied to the Higgs boson acceptance, nor any other jet kinematic variable. We then use this baseline acceptance to scan through possible cuts. Specifically, we consider tagging jet acceptances in intervals of the leading dijet invariant mass $m_{12} = \sqrt{(p_1 + p_2)^2}$, and the leading jet pair rapidity separation $\Delta y_{12} = |y_1 - y_2|$,

$$\begin{aligned} m_{12} > m_{12}^{\text{cut}} \in \{0, 100, 200, 300, 400, 500, 600\} \text{ GeV}, \\ \Delta y_{12} > \Delta y_{12}^{\text{cut}} \in \{0, 1, 2, 3\}. \end{aligned} \quad (1)$$

The central renormalization, μ_R , and factorization, μ_F ,

scales are chosen to be $H_\perp(\text{jets})$, which we here define as

$$H_\perp = \frac{1}{2} \sum_{\substack{i \in \text{jets} \\ (p_\perp > 15 \text{ GeV})}} p_{\perp,i}, \quad (2)$$

where jets are clustered as outlined above, and only subject to a reduced transverse momentum cut with $q_\perp = 15 \text{ GeV}$, which is required to make the scale definition infrared and collinear safe. Note that the jet cuts in the scale definition are more inclusive than the analysis jet cuts.

The full calculation contains Higgs-*Strahlung* (VH) topologies, which interfere with the possible VBF-type diagrams, as depicted in Fig. 1. While we expect these contributions not to be relevant within tight VBF selection criteria, they might well contribute when relaxing these constraints and as such yield a biased view on quantifying the accuracy of the VBF approximation. Simulations used by experimentalists also use a mix of VH and VBF processes, but without interferences and without the pentagon (Fig. 1) and hexagon topologies, implying that biased simulations go into experimental decisions and interpretation.

To work as closely as possible to the simulations used by experimentalists we remove the VH contributions by applying a resonance-veto on any single- and multi-jet masses in the neighborhood of the W^\pm and Z masses, *i.e.*,

$$m_V - \delta m_V < m_{jets} < m_V + \delta m_V \quad (3)$$

with $V = W^\pm, Z$. We choose $\delta m_Z = \delta m_W = 5 \text{ GeV}$. We discuss results both with, and without such a cut applied. All analyses have been performed using a dedicated analysis implemented in Rivet [57].

Impact of QCD corrections – For the inclusive selection, QCD corrections have been found to be moderate for Higgs kinematics but significant for third jet properties, specifically in the high- $p_{\perp,3}$ regime [37]. The approximate calculation suggests small corrections with a significant reduction in scale uncertainty. Prior to studying the differences between the exact and the approximate calculations, we have investigated the effect of QCD corrections subject to tight VBF cuts, implemented by requesting a rapidity gap of $\Delta y_{12} > 3$ and a invariant mass of $m_{12} > 600 \text{ GeV}$ for two tagged jets. We find that NLO corrections in the VBF region are small, and the full and approximate calculations are in reasonable agreement within 3%, with scale variations increasing by 8% upon vetoing on resonant structures.

Shown in the top panel of Fig. 2 is the NLO (solid) and LO (dotted) transverse momentum spectrum $p_{\perp,3}$ of the third jet for the full calculation with $m_{12}^{\text{cut}} = 0 \text{ GeV}$, no resonance-veto cut applied and several choices of $\Delta y_{12}^{\text{cut}}$. The bands represent the NLO scale uncertainty in the range $H_\perp/2 \leq \mu_F = \mu_R \leq 2H_\perp$.

FIG. 2. QCD corrections on the third jet transverse momentum $p_{T,3}$ spectrum for the full and approximate calculations for $m_{12}^{\text{cut}} = 0$ GeV and several choices of $\Delta y_{12}^{\text{cut}}$ (see eq. 1): the predictions for the full calculation, the corresponding differential K -factor and the ratio of the approximated over the full calculation are plotted in the top, middle and bottom panels, respectively. We show LO results (dotted lines), NLO results (solid lines) with scale variations (light bands).

In all of the figures displaying differential cross sections, the middle panel shows differential K -factors, defined as $d\sigma_{\text{NLO}}/d\sigma_{\text{LO}}$, where the bands reflect the NLO scale variations with respect to the leading order calculation fixed at the central scale. The increased K -factor in the high transverse momentum region can be traced back to $VH+1$ jet type events, and the resonance veto has the effect of reducing the corrections down to values of 1.4 in the high transverse momentum region for the inclusive selection cuts ($\Delta y_{12} > 0$) (not shown). In the lower panel of Fig. 2, the ratio of the approximate to the full result is plotted. Differences of order 50% and more are visible when no rapidity separation is required. However, as the rapidity gap increases, the large K -factor in the transverse momentum spectrum for the full calculation is reduced (cf. middle panel), and the full and approximate results display differences at the 20% level in the bulk

FIG. 3. The normalized centralized rapidity y_3^* distribution of the third jet for various leading jet separation rapidity cuts. The upper, middle and lower panel show respectively the full NLO and LO calculation (solid and dotted lines), the K -factor and the ratio of the VBF-approximation to the full NLO result.

of the corrections for $\Delta y_{12} > 0$ (few to ten percent up to $p_{T,3} < 100$ GeV with a resonance-cut applied), and increase up to 50% (30% with a resonance-cut) in the range shown.

In the upper panel in Fig. 3, we consider the normalized centralized rapidity distribution of the third jet $y_3^* = (y_3 - \frac{1}{2}(y_1 + y_2))/|y_1 - y_2|$ without resonance-veto cut for the full NLO calculation as solid lines with scale uncertainty error bands, as well as the LO result (dotted lines). QCD corrections tend to increase for high rapidity separations Δy_{12} . We find a clear improvement of the VBF-approximation for high rapidity separations, whereas it will clearly underestimate the full result if no rapidity separation is required. This observation even holds when resonance-cuts are applied (not shown) with differences in the central and extreme regions of the plot of about 40% for the $\Delta y_{12} > 0$ curve.

Effects of Δy_{12} and m_{12} selections – Fig. 4 depicts the rapidity separation of the two leading jets for several choices of m_{12}^{cut} (left) and the dijet invariant mass of

FIG. 4. The rapidity separation Δy_{12} of the leading two jets, for different cuts on their invariant mass (left) and the jet-jet invariant mass m_{12} as a function of the rapidity gap requirement (right). We compare NLO QCD predictions in the full calculation (solid) to the approximate results (dashed).

FIG. 5. Compatibility of the approximate predictions to the full calculation as a function of VBF acceptance cuts without (left) and with (right) applying vetoes on Higgs-Strahlung-type contributions. We calculate goodness-of-fit measures based on the scale variation uncertainty for a range of observables relevant to the typical VBF kinematics. For the degrees of freedom we count only non-zero bins. Their number ranges from 101 to 129.

the leading two jets for several choices of $\Delta y_{12}^{\text{cut}}$ (right). The resonance-veto described in eq. (3) has been enforced in the event selection contributing to these observables. We again compare NLO results (solid lines) with scale

uncertainty error bands for the full calculation as well as LO results (dotted lines). NLO corrections (K -factors shown in the middle panels) can reach the 40% level for rapidity separation values ≤ 1 and dijet invariant masses

of 100 GeV. Increasing the invariant mass cut m_{12} beyond approximately 100 GeV results in smaller NLO corrections for all rapidity separations (as seen in the right plot of Fig. 4). The quality of the VBF approximation is shown in the lower ratio plots. Deviations of the order of several ten per cent are visible for small rapidity separations and/or small dijet invariant masses. Increasing values of $\Delta^{\text{cut}} y_{12}$ result in better agreement between the full and approximate results (left). However, the full and approximate calculations are not guaranteed to agree in the presence of a cut on the dijet invariant mass alone (right plot with $\Delta y > 0$).

While we have so far only presented a few observables to quantify the impact of QCD corrections and the validity of the VBF approximation, the calculation we performed has actually involved a large number of observables sensitive to the kinematic distribution of the third jet as well as dedicated VBF observables. In order to quantify the quality of the approximation across the whole set of these observables we consider a metric inspired by a statistical test and calculate

$$\chi^2 = \frac{1}{N_{\text{bins}}} \sum_{\text{bins } i} \frac{(\sigma_{i,\text{HJets}} - \sigma_{i,\text{VBF}})^2}{\max(\delta_{\mu}\sigma_i^2, \delta_{\text{stat}}\sigma_i^2)}, \quad (4)$$

where we consider the maximum of scale variation $\delta_{\mu}\sigma_i$ or statistical deviation $\delta_{\text{stat}}\sigma_i$ per bin to set the scale of fluctuations within which we want to measure agreement. The results are presented in Fig. 5, where we include $p_{T,3}$, y_3^* , y_h^* , $\Delta y_{h,12}$, $\Delta\phi_{h,12}$, and m_{123} in the goodness-of-fit calculation as a function of $\Delta^{\text{cut}} y_{12}$ and m_{12}^{cut} without (left column) and with (right column) the resonance-veto on the Higgs-Strahlung-type events Eq. (3). We can clearly observe that the VBF approximation can be considered valid only for dijet invariant mass cuts above 500 GeV and for rapidity gaps above 2. It would seem as if the VBF cuts do not remove the HVj events effectively even in tight VBF selections. In contrast, for the resonance-veto case agreement starts near $m_{12} = 500$ GeV and a rapidity gap of 0, however only a rapidity gap cut of at least 2 units guarantees decent agreement between the full and approximate calculations.

Conclusions and outlook – In this letter, we have addressed the quality of the vector boson fusion approximation in three jet events by comparing full and approximate calculations at NLO QCD. While moderate rapidity separation cuts guarantee convergence at the percent level, large dijet invariant mass cuts are not sufficient to achieve the same accuracy. This important information should be taken into account in experimental analyses. In addition, we have shown that the NLO QCD corrections of the full calculation can reach a factor of 3 and are consistent with Higgs-Strahlung VHj contributions.
